Received 6 September 2010; revised 12 February 2011; accepted 1 March 2011; published 25 May 2011.

1 Phyllosilicates on Mars mapped by infrared spectroscopic techniques could have been affected by dehydration and/or dehydroxylation associated with chemical weathering in hyperarid conditions, volcanism or shock heating associated with meteor impact. The effects of heat-induced dehydration and/or dehydroxylation on the infrared spectra of 14 phyllosilicates from four structural groups (kaolinite, smectite, sepiolite-palygorskite, and chlorite) and two natural zeolites are reported here. Pressed powders of size-separated phyllosilicate and natural zeolite samples were heated incrementally from 100°C to 900°C, cooled to room temperature, and measured using multiple spectroscopic techniques: midinfrared (400–4000 cm⁻¹) attenuated total reflectance, midinfrared reflectance (400–1400 cm⁻¹), and far-infrared reflectance (50–600 cm⁻¹) spectroscopies. Correlated thermogravimetric analysis and X-ray diffraction data were also acquired in order to clarify the thermal transformation of each sample. For phyllosilicate samples, the OH stretching (~3600 cm⁻¹), OH bending (~590–950 cm⁻¹), and/or H₂O bending (~1630 cm⁻¹) bands all become very weak or completely disappear upon heating to temperatures > 500°C. The spectral changes associated with SiO₄ vibrations (~1000 cm⁻¹ and ~500 cm⁻¹) show large variations depending on the compositions and structures of phyllosilicates. The thermal behavior of phyllosilicate IR spectra is also affected by the type of octahedral cations. For example, spectral features of Al³⁺-rich smectites are more stable than those of Fe³⁺-rich smectites. The high-temperature (>800°C) spectral changes of trioctahedral Mg²⁺-rich phyllosilicates such as hectorite, saponite, and sepiolite result primarily from crystallization of enstatite. Phyllosilicates with moderate Mg²⁺ concentration (e.g., palygorskite, clinochlore) and dioctahedral montmorillonites (e.g., SAz-1 and SCa-3) with partial Mg²⁺-for-Al³⁺ substitution all have new spectral feature developed at ~900 cm⁻¹ upon heating to 800°C. Compared with phyllosilicates, spectral features of two natural zeolites, clinoptilolite and mordenite, are less affected by thermal treatments. Even after heating to 900°C, the IR spectral features attributed to Si (Al)-O stretching and bending vibration modes do not show significant differences from those of unheated zeolites.

fit. Still there is no definitive evidence in TES data showing that clay minerals dominate any particular geographic region of Mars or are globally distributed because it is difficult to distinguish phyllosilicates from other high silica phases in TES data at global scale [Bandfield, 2002; Ruff, 2003; Michalski et al., 2005, 2006; Ruff and Christensen, 2007]. Recent studies show it can be possible to identify phyllosilicates at local scales: thermal emission spectra can be used to delineate phyllosilicate deposits from their long-wavelength spectra features [Ruff and Christensen, 2007; Michalski et al., 2010]. However, in general TES spectra of the same deposits where OMEGA and CRISM delineate phyllosilicate occurrences do not show unambiguous evidence for these minerals. One reason for this disconnect could be that Martian phyllosilicates could have structures modified by postdepositional processes which would affect near infrared and thermal infrared spectral processes in different ways.

[4] Phyllosilicates detected on the surface of Mars have been primarily dated as early-to-mid Noachian in age [Bibring et al., 2005; Poulet et al., 2005; Mustard et al., 2007], which suggests phyllosilicates on Mars may have been altered by multiple processes (e.g., chemical weathering in hyperarid conditions, volcanism or shock heating associated with meteor impact). Impact events may be one of the most important processes that affected phyllosilicates. It is possible that the phyllosilicates were repeatedly subjected to high temperatures resulting from impact processes and continuous exposure to high temperatures is likely to lead to the dehydration and/or dehydroxylation of phyllosilicates. Both their structural properties and spectral features could have been modified significantly by high temperature and pressure induced by impact shocking. Previous studies showed suggestive evidence of dehydrated and/or dehydroxylated phyllosilicates on Mars.

[5] Mawrth Vallis has been studied by several authors because this region is potentially significant for understanding the different climatic and geologic environments of ancient Mars [Poulet et al., 2005; Michalski and Noel Dobrea, 2007; Loizeau et al., 2007; Bishop et al., 2008a, 2009; Farrand et al., 2009; Michalski and Fergason, 2009]. The distribution of phyllosilicates detected near Mawrth Vallis corresponds to the light-toned deposits in the surrounding Noachian plains [Loizeau et al., 2007]. However, Loizeau et al. [2007] noticed a lack of phyllosilicates on a few bright outcrops near Mawrth Vallis. For example, they did not find any evidence showing the presence of phyllosilicates on a bright outcrop which was located on the west of Mawrth Vallis. Processes of dehydration and/or dehydroxylation were among the reasons they hypothesized to explain this observation. Michalski and Noel Dobrea [2007] also pointed out that all the phyllosilicates identified near Mawrth Vallis are associated with light-tone bedrock, but not all light-toned bedrock contains phyllosilicates. Milliken et al. [2007] calculated and produced a hydration map for Mawrth Vallis region by examining the strength of the ~3 μm absorption of OMEGA data. The estimated water content of the bright outcrop without phyllosilicate detection as described by Loizeau et al.’s [2007] work is significantly less than that of the bright outcrops mantled by phyllosilicates, but still higher than surrounding terrains with similar albedo values. This result is consistent with the possibility that the outcrop on the west of Mawrth Vallis is covered by dehydrated and/or dehydroxylated phyllosilicates.

[6] A recent study by Gavin and Chevrier [2010] showed that near-infrared spectral features from the ejecta of Toro crater are more consistent with those of thermally treated nontronite. Fairén et al. [2010] calculated the maximum temperature increases in a transient crater and their model showed that temperatures can reach as high as 1000°C in certain areas. Not only do meteoric impacts induce flash heating of the target, but they also deposit a significant amount of energy into the planetary surface that could lead to longer term heating of the target rocks. In the impact-induced hydrothermal systems modeled by Abramov and Kring [2005], they calculated that temperature as high as 1200°C can last for tens of thousands of years. In the laboratory, temperatures as low as 500–700°C are sufficient to cause the complete dehydration and/or dehydroxylation of most phyllosilicates within 24 h [e.g., Guggenheim and Koster van Groos, 2001]. Examinations of meteorites by several authors suggested that shock heating plays a major role in the modification of phyllosilicates [Ohnishi and Tomeoka, 2002; Tomui et al., 2003; Tomioka et al., 2007]. Relatively little work has been done to systematically analyze the effects of shock on phyllosilicates, though previous authors demonstrated that phyllosilicates (serpentine, nontronite) do in fact lose volatiles due to shock pressures and shock heating [Boslough et al., 1980; Lange and Ahrens, 1982]. In addition, serpentines that have not lost their OH during shock appear to be more susceptible to dehydroxylation postshock than their unshocked counterparts, as a result of increased disorder in their structures [Tübnészcz and Ahrens, 1988]. Recent work on near infrared (NIR) spectroscopy of a shocked sample of nontronite revealed few spectral changes as a function of impactor velocity [Gavin et al., 2008], but this work did not provide details on the interpreted shock pressures or the amount of volatile loss. All of the previous work shows, however, that volatile loss in phyllosilicates occurs as a result of shock pressure. The combined effects of shock heating and shock pressure are difficult to analyze together in the laboratory. However, these effects can be analyzed independently, and the effects of heat-induced dehydroxylation and/or dehydroxylation are analyzed here.

[7] The objective of this study is to characterize the mid-tofar-IR spectral features of phyllosilicates from four groups (smectite, kaolinite, chlorite, and sepiolite-palygorskite) that have been heated to increasingly higher temperatures in order to gain insights into the crystal structures of phyllosilicates at different temperatures and to enable future identification of these types of minerals on Mars. A subsequent paper will examine the effect of dehydration and/or dehydroxylation on visible and near IR (VNIR) reflectance spectra.

[8] In addition to phyllosilicates, we also analyzed the spectral features of two natural zeolite minerals as a part of this study. Zeolites may be another important class of minerals that are present on the surface of Mars in a hydrated state [Bish et al., 2003]. Ruff [2004] has provided some evidence of zeolites in Martian surface dust using TES data and using CRISM near-infrared spectral data, Ehlmann et al. [2009] identified zeolites in craters west of Nili Fossae. Zeolites have chemical compositions similar to phyllosilicates and they are common hydrous alteration products of
basaltic rocks. Therefore study of both phyllosilicates and zeolites can provide a more comprehensive spectral feature library for dehydrated and/or dehydroxylated aluminosilicate minerals.

2. Background

2.1. Brief Review of Phyllosilicate and Zeolite Structures

The crystal structures of phyllosilicate minerals are well known and only basic information will be provided here in order to provide context for the spectroscopy results [Farmer, 1974; Bailey, 1980; Moore and Reynolds, 1989a].

There are many kinds of phyllosilicates due to the possible structural and chemical variations within this mineral family, but most have the typical layer structures composed of two different kinds of sheets: tetrahedral sheets (T) and octahedral sheets. The dominant cation (normally Si$^{4+}$, Al$^{3+}$, or Fe$^{3+}$) in the tetrahedral sheet(s) is tetrahedrally coordinated to four oxygen anions and the corner–linked tetrahedra extend infinitely in two dimensions. Individual tetrahedral sheets have a composition of T$_2$O$_5$, but the Si/O ratio varies from 0.3 to 0.4 as Si$^{4+}$ cations are replaced by Al$^{3+}$ or Fe$^{3+}$ to various extents. The octahedral sheet can be described as a sheet of edge-linked octahedra, extending infinitely in the same two dimensions as the tetrahedral sheets. The octahedral cations are typically Al$^{3+}$, Mg$^{2+}$, Fe$^{3+}$, or Fe$^{2+}$, but most other transition elements (except Sc) and Li can occur in some minerals. Cations in the octahedral sheet are octahedrally coordinated to oxygens and hydroxyls. The tetrahedral sheets and octahedral sheet are linked together by shared apical oxygens to form the layer structures. Unlike the tetrahedra, not all of octahedral sites must be filled by cations. The smallest structural unit contains three octahedra and the number of cations can vary between two and three, to meet the general requirement of a total positive charge of six for these three sites. For example, there could be 3 Mg$^{2+}$ ions or 2 Al$^{3+}$ ions in the octahedral sites. When three ions are present, the structure is called trioctahedral, and if only two of the three sites are occupied, it is called dioctahedral.

Phyllosilicates selected for this study can be divided into four groups according to their structural type: the kaolinite-serpentinite group, smectite group, chlorite group, and sepiolite-palygorskite group. The kaolinite-serpentinite group minerals are characterized by an uncharged 1:1 (one octahedral sheet is linked to one tetrahedral sheet) layers, and they contain no cations or H$_2$O molecules in their interlayers. Minerals of the smectite group are all 2:1 (one octahedral sheet is linked to two tetrahedral sheets, one on each side) layers and they have interlayer cations to balance a negative charge on the 2:1 layers. They also typically contain H$_2$O molecules in their interlayer region. Both dioctahedral and trioctahedral smectite minerals are discussed here. Members of the chlorite group also have a negatively charged 2:1 layer structure, but they have positively charged (R$^2+;R^3+)_n$(OH)$_6$ octahedral sheets in the interlayers instead of large cations and H$_2$O molecules. Sepiolite and palygorskite (also known as attapulgite) also contain 2:1 layers in their structural units but they are different from other phyllosilicates. Sepiolite and palygorskite have similar ribbon-like morphologies and their octahedral and tetrahedral sheets are divided into ribbons by inversion, although the tetrahedral sheets are still linked. The alternating channels between ribbon strips are occupied by H$_2$O molecules and exchangeable cations.

Zeolites are microporous aluminosilicates and their structures have been summarized by Breck [1974a, 1974b, 1980]. Newsam [1986], and Armbruster and Guenter [2001]. Zeolites are composed of (SiO$_4$)$^4$ and (AlO$_4$)$^5$ tetrahedra that share oxygen atoms, and they have chemical compositions similar to phyllosilicates. However, compared with phyllosilicates characterized by layer structures, zeolites have a three-dimensionally linked crystal structure. The (SiO$_4$)$^4$ and (AlO$_4$)$^5$ tetrahedra are linked together to form a framework consisting of interconnected tunnels and cages. Ions of suitable size such as K$^+$, Ca$^{2+}$, and Na$^+$ can enter into the extraframework sites in zeolites, and H$_2$O molecules can also exist inside the porous structures.

2.2. Previous Studies of Dehydration and/or Dehydroxylation of Phyllosilicates and Zeolites

Many techniques have been used to analyze the dehydration and/or dehydroxylation behaviors of phyllosilicates in the past. Infrared (IR) spectroscopy, thermogravimetric analysis (TGA), X-ray diffraction (XRD) analysis, and nuclear magnetic resonance (NMR) spectroscopy are the most important of them.

TGA is the most direct tool to observe the temperature dependence of mineral mass. XRD is the most common technique used to study changes in crystal structure when a mineral is heated or exposed to different atmospheres [e.g., Harris et al., 1992; Aceman et al., 1997; Sarikaya et al., 2000], and NMR spectroscopy can help to follow the changes in the coordination environments of H, Si, Al, and interlayer cations within phyllosilicates and zeolites caused by thermal treatment [e.g., Frost and Barron, 1984; Fitzgerald et al., 1989, 1996; Sanchez-Soto et al., 1993; Carroll et al., 2005; Roch et al., 1998; Drachman et al., 1997; Sanz et al., 1988; Lambert et al., 1989; Rocha and Klinowski, 1990; Slade and Davies, 1991; Massiot et al., 1995; Rocha, 1999; McManus et al., 2001; He et al., 2003]. Of these, TGA and XRD analysis were utilized in this study to complement IR spectroscopy, and NMR will be used in the extension of this present work.

Grim and Kubicki [1961] published IR transmission spectra of about forty montmorillonite–group samples after heating to 1400°C. Bruckenthal and Singer [1987] suggested that dehydrated phyllosilicates may exist on Mars and several asteroids due to the anhydrous nature of the extraterrestrial environment. They reported the NIR reflectance (~0.5–4.5 μm) spectra of hydrated 1:1 and 2:1 layer phyllosilicates (including serpentine, talc, Ca-montmorillonite, and saponite) and their heating products (120, 160, 200, 250, 300, 400, 600, and 750°C), in order to provide information for future spectroscopic observations of other planets. Villieras et al. [1994] used transmission infrared spectroscopy (400–4000 cm$^{-1}$) to study the thermal modifications of chlorite. Further infrared spectroscopic studies of dehydrated and/or dehydroxylated phyllosilicates developed gradually over the past 10 years. Kloprogge et al. [1999a, 1999b, 2000] and Kloprogge and Frost [2005] published a series of reports about emission (400–4000 cm$^{-1}$) analysis of dehydroxylated phyllosilicates including smectite group, kaolinite group,

and chlorite group minerals. However, their technique was considered a transmission measurement according to the different definitions of radiance and emissivity [Michalski et al., 2006]. Milliken and Mustard [2005] acquired reflectance spectra (1.3–5.0 μm) of five hydrated materials (including montmorillonite and clinoptilolite) at different temperatures in order to quantify the H₂O content of hydrated minerals. Gavin and Chevrier [2010] thermally treated nontronite and montmorillonite and used NIR (1.0–2.5 μm) reflectance spectra to characterize the structural changes occurring on heating. They showed that high-temperature (above 1000°C) heating causes all NIR spectral features to disappear.

Most studies of the dehydration of natural zeolites have been based on thermogravimetric analysis (TGA), differential thermal analysis (DTA), and XRD measurements. The extraframework cation compositions [Bish, 1988], the energetics of the H₂O in the zeolite channels [Bish and Carey, 2001], the Si/Al ratio of a zeolite, and the ionic potential [Cruciani, 2006] all affect the thermal behavior of natural zeolites significantly. Relatively fewer results have been reported on the infrared spectroscopy of dehydrated natural zeolites. Rodriguez-Fuentes et al.’s [1998] work suggested that the IR spectral features (400–1700 cm⁻¹) of clinoptilolite and heulandite samples were most affected by their exchangeable cation composition and the history of thermal treatment. The dehydration processes of naturally occurring zeolites (including stilbite and mesolite) were investigated by in situ FTIR spectroscopy (400–8000 cm⁻¹) by Prasad et al. [2005] and Prasad and Prasad [2007], who reported the IR absorbance spectra of dehydrated natural zeolites.

2.3. The Significance of This Work

Although the dehydration and/or dehydroxylation behaviors of phyllosilicates and zeolites have been studied extensively in the past, there is no substantive work thoroughly describing the mid-to-far-IR spectral reflectance changes of these minerals upon heating. In section 1, we hypothesized that dehydrated and/or dehydroxylated phyllosilicates due to impact heating may remain on Mars. NIR spectra cannot identify these possible dehydrated and/or dehydroxylated phases because phyllosilicates show almost no spectral feature in near-IR region after they have been heated to high temperatures [Milliken and Mustard, 2005; Gavin and Chevrier, 2010; Che and Glotch, 2010]. Therefore it is very important to understand the effects of temperature on the mid-IR spectra of phyllosilicates.

In this study, we (1) report how the mid-IR attenuated total reflectance (ATR) and mid-to-far-IR specular reflectance spectra of phyllosilicates and zeolites change with exposure to increasingly higher temperatures, All spectra presented in this manuscript will be made available online at “http://aram.ess.sunysb.edu/research.html”; (2) discuss differences in spectral behaviors within and among groups of smectites, sepiolite-palygorskite, kaolinite, chlorites, and zeolites; (3) provide a reference database for future search of the possible existence of dehydrated and/or dehydroxylated phyllosilicates resulting from impact-induced high temperatures on the surface of Mars.

3. Methodology

3.1. Acquisition and Preparation of Samples

Fourteen phyllosilicate and two zeolite samples were selected for this study (Table 1). All samples were purchased from the Clay Minerals Society (CMS) Source Clays repository unless otherwise stated. In addition, two zeolite minerals, mordenite and clinoptilolite, were selected for analysis of their dehydration behavior. Chemical and structure compositions for these samples are summarized in Tables 2 and 3.

To facilitate precise characterization of our samples, a particle size separation method introduced by Moore and Reynolds [1989b] was performed on the phyllosilicates and zeolites in order to remove impurities that occur mostly in the >2 μm size fraction [Moore and Reynolds, 1989b]. As such, all samples described in this study were prepared to <2 μm size fractions prior to heat treatments. The phyllosilicates and zeolites were then heated under normal atmospheric conditions at 100, 200, 300, 400, 500, 600, 700, 800, and 900°C. The heating duration for each temperature was 24 h. All heated products were stored in a desiccator before spectral measurements.

3.2. Thermogravimetric Analysis

Detailed thermal analysis results for most CMS Source Clay samples have been reported as part the baseline studies of the source clays [Guggenheim and Koster van Groos, 2001]. We performed thermogravimetric analysis on all phyllosili-

3.3. Acquisition of Powder XRD Patterns
[22] Powder XRD patterns were acquired for all phyllosilicates and zeolites and their heated products in order to confirm their mineralogy and to observe the crystal structural changes of phyllosilicates and zeolites upon heating. XRD data were measured using a Thermo ARL Scintag PAD-X automated powder diffractometer with Cu-Kα radiation, collecting from 5° to 40° 2θ at a 0.6 degree/minute. Samples for XRD analysis were prepared using the smear-mount method with ground sample powders (http://pubs.usgs.gov/ of/2001/of01-041/html/docs/methods/xslide.htm).

3.4. Infrared Spectroscopic Measurements

[23] Infrared specular reflectance and attenuated total reflectance (ATR) spectra were acquired at Stony Brook University in the Vibrational Spectroscopy Laboratory (VSL) using a Nicolet 6700 FTIR spectrometer.

[24] Specular reflectance peaks are generally referred to as “reststrahlen” features. These occur because the absorption coefficient of a vibrational band is so high that a mirror-like opacity is induced, resulting in strong reflectance from the smooth surface of the samples [Salisbury, 1993]. Midinfrared (400–1400 cm$^{-1}$) and far-infrared specular reflectance (100–600 cm$^{-1}$) spectra were collected for all phyllosilicates and zeolites and their heated products. A gold-coated first surface mirror was used for the reflectance standard. Each sample was pressed in a Carver Hydraulic Press to create a pellet, 13 mm in diameter and about 3 mm in thickness. Spectra from 400 to 1400 cm$^{-1}$ were acquired using a KBr beamsplitter and a thermoelectrically cooled deuterated L-alanine doped triglycerine sulfate (DLaTGS) detector with a KBr window. For each sample, 256 scans in the mid-IR spectral range were recorded with a resolution of 4 cm$^{-1}$. Spectra from 100 to 600 cm$^{-1}$ were acquired using a Thermo Fisher Solid Substrate beamsplitter and a DLaTGS detector with a polyethylene window. A total of 2048 scans and 4 cm$^{-1}$ resolution were used for the far-IR spectral range. All specular reflectance measurements were collected using a Baseline FT-30 accessory with incidence and reflectance angles of 30°. A purge gas system was used to remove CO$_2$ and water vapor from the spectrometer.

[25] Attenuated total reflectance (ATR) measurements in the mid-IR (400–4000 cm$^{-1}$) range were acquired a Nicolet 6700 FTIR spectrometer equipped with a Smart Orbit single bounce ATR accessory with a type II A diamond ATR element which has high refractive index. When IR source radiation enters the ATR element, a total internal reflection occurs and an evanescent wave is formed at the boundary between ATR element and sample. ATR spectra were acquired from unprepared samples rather than pressed pellets because no sample preparation is needed for ATR measurement. The sampling surface is pressed into intimate optical contact with the top surface of ATR crystal and the resulting evanescent wave penetrates only a few microns into the sample. ATR standard was a spectrum with no sample on the ATR element. The resultant spectrum has the similar peak positions to an equivalent absorbance IR spectrum. Because of ATR’s easy sample preparation and effectiveness with small grain size, ATR has been considered a potential in situ IR technique for future planetary explorations [Chentob and Glotch, 2007].

4. Results and Interpretations

4.1. Kaolinite-Serpentine Group

4.1.1. Attenuated Total Reflectance Spectra

[26] The ATR spectra of thermally treated KGa-1b kaolinite samples are shown in Figure 1a. OH-stretching vibration bands were observed at ~3620, 3650, 3660, and 3680 cm$^{-1}$ [Farmer, 1974] for samples heated from 100°C to 400°C. Dehydroxylation was evidenced by a decrease in intensities of OH-stretching vibration bands at 400°C and the disappearance of these bands at 500°C. Corresponding to the changes in the 3650 cm$^{-1}$ band, the OH-deformation bands at ~910 and ~930 cm$^{-1}$ [Madejová and Komadel, 2001] became weaker at 400°C and disappeared at 500°C. The characteristic Si-O stretching vibration bands around 1100, 1020, and 990 cm$^{-1}$ [Madejová and Komadel, 2001] disappeared at 500°C and a new peak at ~1050 cm$^{-1}$ formed after the dehydroxylation process was complete. Characteristic Si-O bending vibrations occurring near 400–550 cm$^{-1}$ [Bishop et al., 2008b] began to change significantly at 400°C and completely disappeared when the sample was heated to 500°C. The relatively weak spectral features near 640–800 cm$^{-1}$ were assigned to Si-O bands [Madejová and Komadel, 2001], which also changed distinctly upon heating to 400°C.

4.1.2. Specular Reflectance Spectra

[27] The effects of dehydroxylation on the KGa-1b kaolinite reflectance spectra (Figure 1b) were similar to those exhibited in ATR spectra. In both cases, the original spectral features of KGa-1b kaolinite were lost at 400°C, and spectral features from dehydroxylated KGa-1b kaolinite were relatively stable from 500°C to 900°C. Spectral features in the specular reflectance data belonging to the original sample all disappeared at 400°C, but the 400°C ATR spectrum of KGa-1b kaolinite retained decreased original spectral feature at ~525 cm$^{-1}$.

[28] Upon heating to 400°C, the SiO$_4$ stretching vibrations occurring at ~1010, ~1060, and ~1130 cm$^{-1}$ [Bishop et al., 2008b] disappeared and were replaced by a new band around 1100 cm$^{-1}$. This new feature continued to shift toward higher wave numbers upon heating (1076 cm$^{-1}$ at 400°C and 1109 cm$^{-1}$ at 900°C). Other significant changes in the mid-IR region (>400 cm$^{-1}$) included the disappearance of the OH deformation vibration bands at ~938 cm$^{-1}$ and 908 cm$^{-1}$ [Bishop et al., 2008b] and Si-O bending vibration bands in the range 400–560 cm$^{-1}$ [Bishop et al., 2008b] at 400°C. A new spectral feature appeared in the Si-O bending region at 400°C and this new peak gradually shifted to higher wave numbers (440 cm$^{-1}$ at 400°C and 460 cm$^{-1}$ at 900°C) upon heating. In the far-IR region (~400 cm$^{-1}$), reflectance peaks occurring at 190, 271, and 345 cm$^{-1}$ were assigned to mixed vibrations which included the Si-O network, octahedral cations, and hydroxyl groups [Farmer, 1974]. As with some spectral features described in the mid-IR region, the bands disappeared at 400°C and no new peaks formed at higher temperatures.

4.1.3. Thermogravimetric and X-Ray Diffraction Analysis

[29] TGA and XRD revealed similar behavior to IR spectroscopy for the dehydroxylation process in kaolinite. TGA data for kaolinite (Figure 1c) showed only one significant weight loss from 400°C to 600°C, associated with the loss of hydroxyl groups. The XRD pattern of kaolinite (Figure 1c) at 500°C showed that the 001 peak disappeared, indicated that the layer structure of kaolinite has been destroyed by 500°C. TGA data for this corresponding temperature range showed a 25 wt% loss due to evolution of H$_2$O from OH groups.

4.2. Smectite Group

4.2.1. Montmorillonite

[30] Four montmorillonite samples of various origins and compositions are discussed in this section. A fifth sample, Syn-1 mica-montmorillonite is discussed later. Although Syn-1 is listed by the Clay Minerals Society as a synthetic...
mica-montmorillonite, previous study [Kloprogge et al., 1999a] indicates that both its chemical composition and spectral features are close to those for beidellite. Therefore, data for Syn-1 will be discussed with the beidellite sample SBCa-1.

4.2.1.1. Attenuated Total Reflectance Spectra

[31] Dehydroxylation of SAz-1 montmorillonite, evidenced by disappearance of its Al-Al-OH deformation band (912 cm⁻¹), Al-Mg-OH deformation band (837 cm⁻¹), and OH stretching bands (3610 cm⁻¹, 3398 cm⁻¹) [Madejová and Komadel, 2001], occurred at 500°C (Figure 2a). The 500°C spectrum of SAz-1 retained a weak 1631 cm⁻¹ H-O-H bending band but this feature disappeared in the 600°C spectrum. Over the same temperature range the 509 cm⁻¹ Al-O-Si deformation band [Madejová and Komadel, 2001] disappeared. Beginning at a temperature of 500°C, the Si-O stretching band at 972 cm⁻¹ became broad and was eventually replaced by two bands at 922 cm⁻¹ and 1059 cm⁻¹ above 700°C. Another Si-O stretching band (longitudinal mode) at ~1126 cm⁻¹ [Madejová and Komadel, 2001] was relatively stable but it disappeared at 800°C. An additional new strong feature began to develop at ~780 cm⁻¹ when SAz-1 montmorillonite was heated to 800°C.

[32] The SCa-3 montmorillonite showed similar spectral behavior to SAz-1 montmorillonite (Figure 2b). The OH-stretching bands (~3610 cm⁻¹ and ~3398 cm⁻¹) disappeared at 600°C and the H-O-H bending band (~1630 cm⁻¹) disappeared at 700°C. The Al-Al-OH deformation band, Al-Mg-OH deformation band, and Al-O-Si deformation band (~910 cm⁻¹, ~842 cm⁻¹, and ~505 cm⁻¹, respectively) disappeared at 500°C. The Si-O stretching band (~970 cm⁻¹) broadened and was replaced by two bands (~1050 cm⁻¹ and ~920 cm⁻¹) at 700°C. The Si-O stretching band (longitudinal mode) gradually shifted to higher wave numbers (~1109 cm⁻¹ at room temperature to ~1138 cm⁻¹ at 700°C) and it disappeared at 800°C. Finally, a new spectral feature at ~780 cm⁻¹ formed at 800°C.

[33] Most OH groups were removed from the STx-1 structure by 500°C, evidenced by disappearance of the Al-Mg-OH deformation (~842 cm⁻¹), Al-Al-OH deformation (~914 cm⁻¹), and OH stretching (3624 cm⁻¹ and 3340 cm⁻¹) bands (Figure 2c). The 515 cm⁻¹ Al-O-Si deformation band

Figure 1. (a) The 400–4000 cm⁻¹ ATR spectra of kaolinite (KGa-1b) calcined at various temperatures. (b) The 100–1500 cm⁻¹ specular reflectance spectra of kaolinite (KGa-1b) calcined at various temperatures. Linear vertical offset is applied to the spectra for clarity. (c) TGA plots and X-ray diffraction profiles (offset) of KGa-1b kaolinite.
disappeared at 500°C, and a new band at \( \sim 567 \text{ cm}^{-1} \) began to develop at 600°C and disappeared at 800°C. The Si-O stretching band experienced a distinct shift toward higher frequencies at 500°C heating (\( \sim 993 \text{ cm}^{-1} \) at room temperature, \( \sim 1074 \text{ cm}^{-1} \) at 900°C) and the weak Si-O stretching (longitudinal mode) band at \( \sim 1126 \text{ cm}^{-1} \) disappeared after 800°C heating. The spectral feature at \( \sim 792 \text{ cm}^{-1} \) was assigned to Si-O stretching of cristobalite [Madejová and Komadel, 2001] and it showed no changes on heating.

The OH-stretching (\( \sim 3624 \text{ cm}^{-1}, \sim 3390 \text{ cm}^{-1} \)), Al-Al-OH deformation (\( \sim 914 \text{ cm}^{-1} \)), and Al-Fe-OH deformation (\( \sim 881 \text{ cm}^{-1} \)) bands disappeared at 600°C, indicating the loss of OH groups (Figure 2d). Upon heating to 800°C, the 989 cm\(^{-1}\) Si-O stretching band of SWy-2 montmorillonite shifted to higher frequencies, to \( \sim 1065 \text{ cm}^{-1} \) at 900°C. The 1117 cm\(^{-1}\) Si-O stretching (longitudinal mode) band became weaker with an increase in temperature and it disappeared above 800°C. The 513 cm\(^{-1}\) Al-O-Si deformation band disappeared at 600°C and a new peak at \( \sim 561 \text{ cm}^{-1} \) began to grow at this temperature. This new peak disappeared at 800°C. The 777 cm\(^{-1}\) and 796 cm\(^{-1}\) bands were assigned to Si-O stretching modes of quartz admixture [Madejová and Komadel, 2001], and were not affected by the heating treatment.

### 4.2.1.2. Specular Reflectance Spectra

[34] The unspecified clay types (SAz-1 and SCa-3) had similar reflectance spectral behaviors when they were heated (Figures 3a and 3b), and three stages of spectral change were observed. There was no distinct spectral change from 100°C to 400°C, although the spectra showed minor increases in intensity and high-frequency shifting of the Si-O stretching (longitudinal mode) band (\( \sim 1153 \text{ cm}^{-1} \) for SAz-1, \( \sim 1149 \text{ cm}^{-1} \) for SCa-3). From 500°C to 700°C, the Si-O stretching region was dominated by two broad peaks (\( \sim 1153 \text{ cm}^{-1} \) and \( \sim 1061 \text{ cm}^{-1} \) for SAz-1, \( \sim 1149 \text{ cm}^{-1} \) and \( \sim 1057 \text{ cm}^{-1} \) for SCa-3). The Si-O bending region showed more significant changes than the Si-O stretching region over this temperature range. The original doublet feature at

---

**Figure 2.** The 400–4000 cm\(^{-1}\) ATR spectra of (a) “Cheto” montmorillonite (SAz-1), (b) montmorillonite (Otay) (SCa-3), (c) Texas montmorillonite (STx-1), and (d) Na-montmorillonite (Wyoming) (SWy-2) calcined at various temperatures. Linear vertical offset is applied to the spectra for clarity.
∼500 cm\(^{-1}\) was completely lost and was replaced by a strong band with complex shoulder spectral features (∼486 cm\(^{-1}\) for SAz-1, ∼487 cm\(^{-1}\) for SCa-3). The original 327 cm\(^{-1}\) spectral feature in the far-IR region disappeared and a new peak formed at ∼302 cm\(^{-1}\) for both SAz-1 and SCa-3 samples. After heating to 800°C and 900°C, multiple spectral features for SAz-1 and SCa-3 combined to form a single strong peak for both Si-O stretching and bending regions. A new strong band (∼933 cm\(^{-1}\) for SAz-1, ∼927 cm\(^{-1}\) for SCa-3) also developed in this temperature range.

[36] The reflectance spectra of STx-1 montmorillonite and its heating products are displayed in Figure 3c. The 500°C heat treatment produced significant spectral changes. The doublet feature at ∼500 cm\(^{-1}\) caused by Si-O bending modes and the ∼330 cm\(^{-1}\) peak in the far-IR region disappeared. Two bands at ∼1100 cm\(^{-1}\) due to Si-O stretching vibrations shifted away from each other, and new spectral features caused by heating were observed at ∼565 cm\(^{-1}\), ∼484 cm\(^{-1}\), and 302 cm\(^{-1}\). Upon heating to 800°C, all new spectral features formed at lower temperatures disappeared, and two strong reflectance bands at ∼1105 cm\(^{-1}\) and ∼470 cm\(^{-1}\) dominated the mid-IR and far-IR regions of the STx-1 montmorillonite spectra.

[37] In the case of the Swy-2 montmorillonite, two spectral features associated with Si-O stretching around 1070 cm\(^{-1}\) and 1130 cm\(^{-1}\) broadened and shifted away from each other at 600°C and they were replaced by a band near 1107 cm\(^{-1}\) (Figure 3d) at 800°C. A new shoulder feature near 1130 cm\(^{-1}\) formed at 200°C and disappeared at 500°C. New reflectance peaks at ∼568 cm\(^{-1}\) and ∼484 cm\(^{-1}\) appeared at 600°C and the
Al-O-Si deformation (∼534 cm⁻¹) and Si-O-Si deformation (474 cm⁻¹) bands disappeared completely at this temperature. However, these new peaks disappeared at 800°C and a new strong reflectance band appeared at ∼462 cm⁻¹. Distinct spectral changes also occur at 600°C and 800°C in the far-IR region (<400 cm⁻¹), evidenced by disappearance of the original 335 cm⁻¹ feature and formation of a new 302 cm⁻¹ band at 600°C. All of these spectral features disappeared at 800°C. Spectral features at 775 cm⁻¹, 795 cm⁻¹, 393 cm⁻¹, and 366 cm⁻¹ are related to quartz admixture [Madejová and Komadel, 2001] and they persisted through the dehydration and dehydroxylation of SWy-2 montmorillonite.

4.2.1.3. Thermogravimetric and X-Ray Diffraction Analysis

[38] SAz-1 “Cheto” montmorillonite and SCA-3 montmorillonite (Otay) have similar thermal behaviors, related to their identical structures and similar chemical compositions [Grim and Kulbicki, 1961]. Two distinct changes in the TGA curves (Figures 4a and 4b) were observed for both montmorillonites, consistent with the fact that they contain both molecular H₂O and hydroxyl groups in their structures. The dehydration processes, as evidenced by abrupt weight losses at ∼100°–200°C, indicate that both samples began to lose H₂O rapidly from the beginning of heat treatment. Both montmorillonites began to lose their structural OH groups gradually from 600°C to 700°C. XRD data showed that these two montmorillonites retained their original 001 reflection positions at 300°C, and the TGA results indicated that most of their interlayer H₂O molecules were lost by 200°C. The reason may be related to the details of our experimental process for both phyllosilicates and zeolites as heated samples were not protected from rehydration during XRD measurements [e.g., Gavin and Chevrier, 2010]. The XRD results showed that these two montmorillonites were capable of reabsorbing H₂O from the air after heating to 300°C. The d-spacing of the 001 reflections decreased at 500°C showing structural collapse, and at 800°C the 001 reflections disappeared, indicating that the layer structures of SAz-1 and SCA-3 montmorillonites had been destroyed.

[39] STx-1 montmorillonite (Figure 4c) has a lower overall content (∼14%) of OH and H₂O (Table 2) in its structure than SAz-1 (∼21%) and SCA-3 (∼19%), due primarily to differences in exchangeable-cation composition. The STx-1 montmorillonite dehydroxylated more rapidly at higher temperatures (∼700°C) than the other two montmorillonites (∼650°C). Otherwise, the dehydration and dehydroxylation processes of STx-1 montmorillonite manifested in TGA and XRD results (Figure 4c) are similar to those of SAz-1 and SCA-3 montmorillonites.

Figure 4. TGA plots and X-ray diffraction profiles (offset) of (a) SAz-1 “Cheto” montmorillonite, (b) SCA-3 montmorillonite (Otay), (c) STx-1 Texas montmorillonite, and (d) SWy-2 Na-montmorillonite (Wyoming).
40 SWy-2 montmorillonite is the most stable among the four montmorillonites examined here. The 001 reflection of SWy-2 remained as a weak peak at 800°C (Figure 4d), indicating that dehydroxylation at this point was incomplete.

4.2.2. Saponite

4.2.2.1. Attenuated Total Reflectance Spectra

The spectral features at \( \sim 3678 \text{ cm}^{-1} \), \( \sim 3625 \text{ cm}^{-1} \), and \( \sim 3410 \text{ cm}^{-1} \) were assigned to Mg-O-H stretching, Al-O-H stretching, and H-O-H stretching modes, respectively [Van der Marel and Beutelspacher, 1976]. The Al-O-H stretching and H-O-H stretching bands disappeared at 200°C but the Mg-O-H stretching feature persisted to 700°C (Figure 5a), indicating that most of the OH groups in the saponite (SapCa-2) structure were lost around 700°C. Correspondingly, the Mg-OH libration band at \( \sim 650 \text{ cm}^{-1} \) [Van der Marel and Beutelspacher, 1976] was observed only to 700°C. The H\(_2\)O bending band near 1630 cm\(^{-1}\) disappeared at 600°C. No distinct change occurred for Si-O stretching bands (\( \sim 1080 \text{ cm}^{-1} \) and \( \sim 950 \text{ cm}^{-1} \)) until 700°C. Upon heating to 800°C, the original Si-O stretching bands disappeared and were replaced by multiple spectral features between 850 and 1200 cm\(^{-1}\), and similar changes were seen between 600 cm\(^{-1}\) and 750 cm\(^{-1}\) at this temperature.

4.2.2.2. Specular Reflectance Spectra

Similar to the ATR spectra for SapCa-2 saponite, the reflectance spectra did not show any distinct change until 700°C (Figure 5b), although the intensity of the weak Si-O stretching band at \( \sim 1115 \text{ cm}^{-1} \) increased gradually with temperature. The 800°C and 900°C reflectance spectra of saponite exhibited completely different features from those at 700°C. Spectral ranges from 800 cm\(^{-1}\) to 1200 cm\(^{-1}\) and from 200 cm\(^{-1}\) to 600 cm\(^{-1}\) were both dominated by complex multiple bands at 800°C and 900°C.

4.2.2.3. Thermogravimetric and X-Ray Diffraction Analysis

TGA data (Figure 5c) for SapCa-2 saponite showed that most interlayer H\(_2\)O molecules were lost below 150°C, whereupon saponite remained relatively stable until
gradually became weaker as temperature increased. The 980 cm$^{-1}$ Si-O stretching band was stable until 800°C and was replaced by a new spectral feature (~1024 cm$^{-1}$) at 900°C. The 519 cm$^{-1}$ Al-O-Si bending band began to shift gradually toward higher wave numbers (~524 cm$^{-1}$ at 400°C and ~553 cm$^{-1}$ at 800°C) after heating to 400°C and it was replaced by a weak band at ~547 cm$^{-1}$ at 900°C.

[45] The dehydroxylation of Syn-1 montmorillonite was essentially complete around 600°C, as evidenced by the disappearance of the OH-stretching band at ~3629 cm$^{-1}$ in the 600°C ATR spectrum (Figure 6b). The 1635 cm$^{-1}$ H$_2$O bending feature Syn-1 montmorillonite disappeared at 400°C. The 920 cm$^{-1}$ Al-Al-OH deformation band decreased in intensity at 400°C and disappeared after 700°C heating. The Si-O stretching band at ~976 cm$^{-1}$ disappeared at 400°C and was replaced by a broader band around 1018 cm$^{-1}$, which remained until 900°C. The 518 cm$^{-1}$ feature associated with Si-O-Al bending mode decreased in intensity at 400°C and this weaker band shifted to 562 cm$^{-1}$ at temperatures > 400°C. Syn-1 montmorillonite has ammonium in its interlayer [Kloprogge et al., 1999a] and several spectral changes related to ammonium were observed on heating. Features in the 3300-2800 cm$^{-1}$ and near 1433 cm$^{-1}$ were assigned to stretching and deformation vibrations of NH$_4^+$, respectively [Madejová and Komadel, 2001]. The ammonium was lost at temperatures above 500°C based on the disappearance of these spectral bands.

4.2.3.3. Specular Reflectance Spectra

[46] Significant spectral changes in SBCa-1 beidellite began at 400°C (Figure 7a). The 1125 cm$^{-1}$ and 1057 cm$^{-1}$ Si-O stretching bands began to shift away from each other (1134 cm$^{-1}$ and 1045 cm$^{-1}$ at 400°C), the 1015 cm$^{-1}$ Si-O stretching shoulder band disappeared, the 910 cm$^{-1}$ Al-O-H libration band disappeared; the 550 cm$^{-1}$ Si-O-Al bending band [Kloprogge et al., 1998] shifted to higher wave numbers (shifting to 567 cm$^{-1}$ at 500°C), and weak bands in the range 100 cm$^{-1}$ to 400 cm$^{-1}$ were all lost after 400°C heating. A new spectral feature near 300 cm$^{-1}$ formed at 500°C. Then all spectral features, including both the original features and new bands developed at lower temperatures, were completely lost at 900°C. The 900°C reflectance spectrum of SBCa-1 beidellite was dominated by four spectral features at ~1097 cm$^{-1}$, ~796 cm$^{-1}$, 553 cm$^{-1}$, and 462 cm$^{-1}$.

[47] The Si-O stretching bands at ~1122 cm$^{-1}$ and ~1053 cm$^{-1}$ continued to shift away from each other (1142 cm$^{-1}$ and 1045 cm$^{-1}$ at 800°C) as temperature increased and at 900°C they were replaced by a broad band centered near 1097 cm$^{-1}$ (Figure 7b). The weak Al-O-H libration band (~918 cm$^{-1}$) was lost after 400°C heating. The 545 cm$^{-1}$ Si-O-Al bending band shifted to 570 cm$^{-1}$ after 500°C and remained stable to 900°C. The Si-O bending bands at ~480 cm$^{-1}$ and ~420 cm$^{-1}$ shifted slightly away from each other (484 cm$^{-1}$ and 406 cm$^{-1}$ at 900°C) with increasingly higher temperatures and they existed in the 900°C spectrum as features with comparable intensities.

4.2.3.3. Thermogravimetric and X-Ray Diffraction Analysis

[48] SBCa-1 beidellite and Syn-1 mica-montmorillonite both have high Al contents and comparable concentrations of OH and H$_2$O in their structures (Table 2). SBCa-1 exhibited two significant weight losses at ~150°C and ~450°-550°C (Figure 8a), but XRD data indicated that its layer structure...
was stable to at least 800°C. This conflict suggests that dehydration and dehydroxylation did not destroy the crystal structure by this temperature, and beidellite did not transform to an amorphous phase as montmorillonites did at 800°C. Syn-1 mica-montmorillonite experienced the first weight loss in its TGA curve (Figure 8b) from room temperature to \(\sim 150°C\) and the second significant weight loss occurred between 400°C and 650°C. The structure of Syn-1 mica-montmorillonite was also intact to 800°C based on XRD data.

4.2.4. Hectorite

4.2.4.1. Attenuated Total Reflectance Spectra

[50] Heating to 600°C resulted in disappearance of the H-O-H bending band at \(\sim 1624 \text{ cm}^{-1}\) and OH-stretching bands at 3400–3680 \text{ cm}^{-1} (Figure 9a). The single Si-O stretching band at \(\sim 960 \text{ cm}^{-1}\) broadened at 400°C and split into multiple spectral peaks after 500°C heating. Beginning at 600°C, significant change was observed for the Si-O stretching region and a series of new bands (\(\sim 850–1060 \text{ cm}^{-1}\)) formed over this temperature range remained until 900°C. The \(\sim 650 \text{ cm}^{-1}\) and \(\sim 700 \text{ cm}^{-1}\) spectral features were assigned to Mg-OH deformation of SHCa-1 hectorite and the in-plane CO$_3^2-$ bending mode of calcite (existing as a contaminant in the hectorite sample), respectively [Kloprogge et al., 2000]. They both disappeared in the 600°C spectrum and were replaced by two small bands at \(\sim 670 \text{ cm}^{-1}\) and \(\sim 630 \text{ cm}^{-1}\) after 600°C heating.

4.2.4.2. Specular Reflectance Spectra

[50] Specular reflectance results for SHCa-1 hectorite showed that distinct changes due to heating took place around 500°C (Figure 9b). Upon heating to 500°C, the 1047 cm$^{-1}$ Si-O stretching band and the 476 cm$^{-1}$ Si-O bending band both split into multiple bands between 900 and 1070 cm$^{-1}$ and 400–500 cm$^{-1}$ and a series of new spectral features formed in the far-IR region between 200 and 350 cm$^{-1}$.

4.2.4.3. Thermogravimetric and X-Ray Diffraction Analysis

[51] Dehydration and dehydroxylation processes for SHCa-1 hectorite begin at \(\sim 150°C\) and from \(\sim 650°C\) to \(\sim 800°C\), respectively (Figure 9c). However, a unique weight loss around 770°C may be caused by dolomite decarbonation [Guggenheim and Van Groos, 2001]. XRD data show calcite in hectorite even after acid treatment, and the presence of calcite and dolomite may contribute to weight-loss events.
observed by TGA. Compared with the untreated sample, the 500°C XRD pattern of hectorite showed collapse of original layer structure and formation of a new phase. The 800°C XRD pattern of hectorite was consistent with well-ordered enstatite. The transformation from hectorite to enstatite at high temperatures has been summarized previously [e.g., Green et al., 1970; Kloprogge et al., 2000].

4.2.5. Nontronite

4.2.5.1. Attenuated Total Reflectance Spectra

[52] NAu-1 and NAu-2 nontronites are both high-Fe dioctahedral smectites. The major chemical difference between them is a higher Al content in NAu-1 nontronite [Keeling et al., 2000].

[53] The first distinct ATR spectral change in NAu-1 nontronite occurred at 400°C (Figure 10a). Most spectral features related to OH groups [Frost and Kloprogge, 2000; Frost et al., 2002], including the Fe-Fe-OH stretching band (~3560 cm⁻¹), OH stretching of H₂O (~3400 cm⁻¹), Al-Fe-OH deformation band (~908 cm⁻¹), Fe-Fe-OH deformation band (~808 cm⁻¹), and the Mg-Fe-OH deformation band (~742 cm⁻¹), disappeared upon heating to 400°C. The 484 cm⁻¹ Si-O-Fe bending band also disappeared at 400°C. The 1630 cm⁻¹ H₂O bending band became weak at 400°C and was lost at 500°C. A new spectral feature at ~790 cm⁻¹ developed at 500°C and remained until 900°C. The Si-O stretching band near 1000 cm⁻¹ continued to shift toward higher wave numbers (975 cm⁻¹ at room temperature and 1053 cm⁻¹ at 900°C) as temperature increased. In addition, absorption features at ~3695 cm⁻¹ and ~3620 cm⁻¹ were related to kaolinite, which existed in the NAu-1 sample as a contaminant [Keeling et al., 2000], and both bands disappeared at 400°C.

[54] NAu-2 nontronite exhibited spectral behavior upon heating similar to NAu-1 nontronite although the spectra had slightly different band positions (Figure 10b). Most of the original spectral features of NAu-2 nontronite disappeared at 400°C or 500°C; the Si-O stretching band around 1000 cm⁻¹ continued to shift toward higher wave numbers during the heat treatment and new spectral features developed in the range 500 cm⁻¹ to 800 cm⁻¹ upon heating to 600°C. Based on the spectral results, there is no kaolinite in the NAu-2 nontronite.

Figure 9. (a) The 400–4000 cm⁻¹ ATR spectra of hectorite (SHCa-1) calcined at various temperatures. (b) The 100–1400 cm⁻¹ specular reflectance spectra of hectorite (SHCa-1) calcined at various temperatures. Linear vertical offset is applied to the spectra for clarity. (c) TGA plots and X-ray diffraction profiles (offset) of SHCa-1 hectorite.
4.2.5.2. Specular Reflectance Spectra

Two distinct spectral changes took place around 300°–400°C and 700°–800°C for both nontronite samples (Figures 11a and 11b) as they were heated. The spectral features in the 200–400 cm\(^{-1}\) region related to mixed vibrations of the Si-O network \[Farmer, 1974\] and bands around 850 cm\(^{-1}\) associated with OH deformation modes \[Frost and Kloprogge, 2000; Frost et al., 2002\] were all lost after 400°C heating. Multiple Si-O bending bands near 500 cm\(^{-1}\) disappeared and a new band formed (∼460 cm\(^{-1}\) for NAu-1 nontronite, ∼470 cm\(^{-1}\) for NAu-2 nontronite). The Si-O stretching bands of NAu-1 and NAu-2 nontronites near 1050 cm\(^{-1}\) displayed changes similar to each other at 400°C by combining and forming one single band. After 800°C, these new bands in the Si-O stretching and bending regions both shifted slightly to higher frequencies and new spectral features developed in the range 600–800 cm\(^{-1}\). In addition, a weak spectral band in the far-IR region (<400 cm\(^{-1}\)) around 310 cm\(^{-1}\) appeared for both NAu-1 and NAu-2 nontronites at 400°C and it remained until 900°C.

4.2.5.3. Thermogravimetric and X-Ray Diffraction Analysis

[TG] TGA data for nontronite samples NAu-1 and NAu-2 showed their first distinct weight loss below ∼200°C and the loss occurred from ∼400°C to ∼600°C (Figures 12a and 12b). XRD data for the nontronites indicated that their layer structures were destroyed by 800°C. Simultaneously, new features appeared in the XRD patterns (∼35°, 2θ) for both NAu-1 and NAu-2 nontronites, indicating crystallization of new phases.

4.3. Chlorite Group

4.3.1. Attenuated Total Reflectance Spectra

Upon heating to 500°C, OH-stretching bands (∼3678 cm\(^{-1}\), ∼3535 cm\(^{-1}\), ∼3373 cm\(^{-1}\)) disappeared

Figure 10. (a) The 400–4000 cm\(^{-1}\) ATR spectra of nontronite (NAu-1) calcined at various temperatures. (b) The 400–4000 cm\(^{-1}\) ATR spectra of nontronite (NAu-2) calcined at various temperatures. Linear vertical offset is applied to the spectra for clarity.

4.2.5.2. Specular Reflectance Spectra

Two distinct spectral changes took place around 300°–400°C and 700°–800°C for both nontronite samples (Figures 11a and 11b) as they were heated. The spectral features in the 200–400 cm\(^{-1}\) region related to mixed vibrations of the Si-O network \[Farmer, 1974\] and bands around 850 cm\(^{-1}\) associated with OH deformation modes \[Frost and Kloprogge, 2000; Frost et al., 2002\] were all lost after 400°C heating. Multiple Si-O bending bands near 500 cm\(^{-1}\) disappeared and a new band formed (∼460 cm\(^{-1}\) for NAu-1 nontronite, ∼470 cm\(^{-1}\) for NAu-2 nontronite). The Si-O stretching bands of NAu-1 and NAu-2 nontronites near 1050 cm\(^{-1}\) displayed changes similar to each other at 400°C by combining and forming one single band. After 800°C, these new bands in the Si-O stretching and bending regions both shifted slightly to higher frequencies and new spectral features developed in the range 600–800 cm\(^{-1}\). In addition, a weak spectral band in the far-IR region (<400 cm\(^{-1}\)) around 310 cm\(^{-1}\) appeared for both NAu-1 and NAu-2 nontronites at 400°C and it remained until 900°C.

4.2.5.3. Thermogravimetric and X-Ray Diffraction Analysis

[TG] TGA data for nontronite samples NAu-1 and NAu-2 showed their first distinct weight loss below ∼200°C and the loss occurred from ∼400°C to ∼600°C (Figures 12a and 12b). XRD data for the nontronites indicated that their layer structures were destroyed by 800°C. Simultaneously, new features appeared in the XRD patterns (∼35°, 2θ) for both NAu-1 and NAu-2 nontronites, indicating crystallization of new phases.

4.3. Chlorite Group

4.3.1. Attenuated Total Reflectance Spectra

Upon heating to 500°C, OH-stretching bands (∼3678 cm\(^{-1}\), ∼3535 cm\(^{-1}\), ∼3373 cm\(^{-1}\)) disappeared

Figure 11. (a) The 100–1400 cm\(^{-1}\) specular reflectance spectra of nontronite (NAu-1) calcined at various temperatures. (b) The 100–1400 cm\(^{-1}\) specular reflectance spectra of nontronite (NAu-2) calcined at various temperatures. Linear vertical offset is applied to the spectra for clarity.
Si and sheets, and the loss of OH groups above 400°C and was OH‐shifted toward lower frequency was region \[ \text{also changed} \]. Al‐band absorption band was at 900°C. The peak around 800 cm\(^{-1}\) up to 800°C. At 900°C (Figure 15a). The weak 910 cm\(^{-1}\) and in the Si and complex multiple peaks near 200 all became very weak disappeared at 800°C, and in the 800°C ATR spectrum. The 912 cm\(^{-1}\) and the 910 cm\(^{-1}\) with TGA results. The 001 reflection increased in intensity at 500°C and the other 00l reflections generally decreased in intensity. Clinochlore lost its original structure at 700°C and at 900°C the sample transformed to new phases.

4.4. Selligite-Palygorskite Group

4.4.1. Attenuated Total Reflectance Spectra

[50] In the case of palygorskite (PFl-1), the disappearance of the structural OH‐strecthing bands at 3539 cm\(^{-1}\) and 3616 cm\(^{-1}\) and the 912 cm\(^{-1}\) Al-Al-OH deformation band [Madejová and Komadel, 2001] at 400°C indicates that most of the hydroxyl groups have been removed from the palygorskite structure (Figure 14a). The H\(_2\)O bending band around ~1650 cm\(^{-1}\) shifted to ~1620 cm\(^{-1}\) at 100°C and then maintained its position until 600°C. However, the 1620 cm\(^{-1}\) feature was very weak above 400°C. The Si-O stretching band at 976 cm\(^{-1}\) shifted to 1018 cm\(^{-1}\) above 400°C and was at ~1051 cm\(^{-1}\) at 900°C. The peak around 800 cm\(^{-1}\) was assigned to the Si-O stretching band of quartz [Madejová and Komadel, 2001] and existed throughout the heating process. In addition, two spectral features existed only in certain temperature ranges: the ~870 cm\(^{-1}\) absorption band was present from 400°C to 600°C and the ~940 cm\(^{-1}\) band appeared after palygorskite is heated to 800°C.

[61] The spectral changes of sepiolite (SepSp-1) due to heating can be divided into four steps (Figure 14b): (1) no significant change was observed until 200°C; (2) at 300°C, the H\(_2\)O bending band at ~1660 cm\(^{-1}\) and Si-O stretching band around 1210 cm\(^{-1}\) disappeared and another Si-O stretching band at ~972 cm\(^{-1}\) shifted toward lower frequency (~940 cm\(^{-1}\)); (3) at 400°C, two peaks around 3620 cm\(^{-1}\) and 3560 cm\(^{-1}\) attributed to OH stretching disappeared, along with the 1620 cm\(^{-1}\) H\(_2\)O bending band. Correspondingly, the spectral features around 1000 cm\(^{-1}\) which were due to Si-O stretching vibrations became distinctly different from original spectral features; (4) the OH deformation and translation bands throughout the 600–800 cm\(^{-1}\) region [Frost et al., 2011] disappeared at 800°C, consistent with the disappearance of the 3690 cm\(^{-1}\) OH-stretching band at the same temperature. The Si-O stretching bands around 1000 cm\(^{-1}\) changed significantly after 800°C heating and were replaced by multiple spectral features over the range 900–1200 cm\(^{-1}\).
Figure 13. (a) The 370–4000 cm⁻¹ ATR spectra of clinochlore calcined at various temperatures. (b) The 130–1400 cm⁻¹ specular reflectance spectra of clinochlore calcined at various temperatures. Linear vertical offset is applied to the spectra for clarity. (c) TGA plots and X-ray diffraction profiles (offset) clinochlore.
near ~500 cm\(^{-1}\) took place at ~300°C, and then again around 800°C. The OH-deformation band at ~970 cm\(^{-1}\) became very weak after 300°C heating and disappeared at 800°C. The OH translation bands in the 600–700 cm\(^{-1}\) range also disappeared at 800°C. The spectral features for SepSp-1 sepiolite observed after heating to 800°C, were completely different from those observed at lower temperatures. The spectra were no longer dominated by bands in two major spectral regions due to Si-O stretching (centered at ~1050 cm\(^{-1}\)) and Si-O bending (near ~400–550 cm\(^{-1}\)) and instead contained multiple bands near ~800–1200 cm\(^{-1}\), a number of bands ~500 cm\(^{-1}\), and several minor spectral features in the 200–400 cm\(^{-1}\) range.

### 4.4.3. Thermogravimetric and X-Ray Diffraction Analysis

Both PFI-1 palygorskite and SepSp-1 sepiolite exhibited complex dehydration and dehydroxylation processes in their TGA curves (Figures 16a and 16b). Palygorskite lost weight in multiple steps, below ~150°C, from ~150°C to ~280°C, and from ~280°C to 500°C. Sepiolite showed even more complex weight loss behavior than palygorskite, with four overlapping events at ~150°C, from 150°C to 350°C, from 350°C to 550°C, and from 550°C to 850°C. The high temperature phases of palygorskite and sepiolite have been described in many previous studies [e.g., Kulbicki, 1959], which showed that both palygorskite and sepiolite transform to enstatite upon heating to 800°C or elevated temperatures. In this study, the formation of enstatite was apparent in the 800°C XRD pattern of sepiolite because main reflections of enstatite (610) (31°, 2θ) and (420) (28°, 2θ) were recorded, while no clear evidence in the 800°C XRD pattern of palygorskite showed the development of enstatite structure.
4.5. Zeolite Group

4.5.1. Attenuated Total Reflectance Spectra

The infrared spectra of zeolites were summarized by Breck [1974b]. 27031 clinoptilolite lost its H₂O bending (~1630 cm⁻¹) feature at 800°C (Figure 17a). The spectral feature at ~1000 cm⁻¹ due to tetrahedron asymmetric stretching mode showed no obvious change upon heating, although the band became weaker and broader at 800°C. The 790 cm⁻¹ peak was assigned to the stretching modes involving mainly the tetrahedral atoms and remained until 900°C. The bands at ~500–650 cm⁻¹ related to the double rings in the framework structures and the internal tetrahedral symmetric stretching bands over the range ~650–720 cm⁻¹ all disappeared at 800°C.

The spectral behavior of 27133 mordenite (Figure 17b) was similar to that of 27031 clinoptilolite upon heating. However, the OH-stretching bands near 3400 cm⁻¹ and the H₂O bending band at ~1630 cm⁻¹ persisted to 800°C, although they were very weak at higher temperatures.

4.5.2. Specular Reflectance Spectra

The tetrahedral stretching band (~1086 cm⁻¹) of clinoptilolite showed no change until 700°C, and it shifted slightly to higher wave numbers (~1100 cm⁻¹) at 800°C (Figure 18a). Also a weak shoulder band at ~1200 cm⁻¹ developed at 800°C. The weak band at ~780 cm⁻¹ associated with symmetric stretching of external linkages persisted to 900°C. The ~600 cm⁻¹ double-ring band disappeared at 800°C. The Si (Al)-O bending band at ~470 cm⁻¹ remained to 900°C. The weak shoulder band at ~378 cm⁻¹, related to the motion of the tetrahedral rings which form the pore openings in the zeolites [Breck, 1974b] disappeared at 700°C.

The two adjacent tetrahedron stretching bands around 1050 cm⁻¹ (Figure 18b) combined at 500°C and this new band shifted to 1100 cm⁻¹ at 700°C. Two weak spectral features at ~550 and ~625 cm⁻¹ appeared upon heating to 700°C and disappeared at 900°C. Other than these, the 1250 cm⁻¹ Si (Al)-O stretching band, the 770 cm⁻¹ stretching band of external linkages, and the 470 cm⁻¹ Si (Al)-O bending band were remained to 900°C. No spectral features were observed in the far-IR range for mordenite.

Figure 19. TGA plots and X-ray diffraction profiles (offset) of (a) 27031 clinoptilolite and (b) 27133 mordenite.
4.5.3. Thermogravimetric and X-Ray Diffraction Analysis

[69] TGA data for clinoptilolite and mordenite show a slow and continuous loss in weight throughout the heat treatments (Figures 19a and 19b), showing that these two natural zeolites release H₂O from their rigid cage structures gradually upon heating. The XRD results show that the mordenite structure is not affected significantly by 800°C heating whereas clinoptilolite transformed to an amorphous phase at 800°C.

5. Discussion

5.1. Effect of Adsorbed H₂O

[70] For most phyllosilicates analyzed here, TGA result showed that H₂O loss occurred at a low temperature (~200°–300°C), while ATR spectra revealed a much higher temperature (~400°–500°C) for the disappearance of the ~1630 cm⁻¹ H₂O bending band. For example, the H₂O molecules of ScA-3 montmorillonite were lost by 200°C based on its TGA result (Figure 4b) whereas the H–O–H bending band of this montmorillonite was observed from its ATR spectrum up to 500°C (Figure 2b). This conflict is very likely due to the readsoption of water onto the sample because, during ATR measurements, the sample was exposed to open air for 5 min and phyllosilicates have extremely high specific surface area [e.g., Dogan et al., 2006]. Therefore the evolution of the ~1630 cm⁻¹ hydration band in ATR spectrum shows the change of the specific surface area due to heating treatment rather than the dehydration processes of phyllosilicates.

5.2. Effect of Octahedral Cations

[71] The concentration of Al³⁺ or Fe³⁺ in dioctahedral smectites may affect their spectral behaviors on heating. Syn-1 mica-montmorillonite and SBCa-1 beidellite contain the highest concentrations of Al³⁺ (36.75% and 30.71% Al₂O₃, respectively) in octahedral sites, and their IR spectra, particularly the multiple bands in the Si-O bending regions, did not show significant change until 800°C. The montmorillonite series includes four samples in this study: SWy-2 (20.12% Al₂O₃), STx-1 (16.17% Al₂O₃), SAz-1 (17.20% Al₂O₃), and ScA-3 (12.47% Al₂O₃). The first distinct spectral change upon heating occurred around 600°C for SWy-2, whereas the spectra of the three other montmorillonites changed significantly around 500°C. NAu-1 and NAu-2 nontronites are both Fe³⁺ rich smectites, and they lost their original spectral features completely at 400°C. According to the above observations, Al-rich smectites may have greater thermal stability and maintain their spectral features to higher temperatures than Fe-rich smectites, which was also shown by previous investigators Gavin and Chevrier [2010].

[72] Mg phyllosilicates tend to transform to an enstatite phase at ~800°C [e.g., Kubicki, 1959]. The 800°C IR spectral features of the trioctahedral phyllosilicates hectorite, saponite, and sepiolite were completely different from the original spectral features that were dominated by Si-O stretching and Si-O bending bands, indicating the formation of a new phase, likely an enstatite structure. It was also observed that high-Mg phyllosilicates clinohore (23.56% MgO) and palygorskite (9.52% MgO), moderate-Mg smectites SAz-1 (5.80% MgO) and ScA-3 (8.55% MgO) montmorillonites, and even low-Mg STx-1 (3.43% MgO) montmorillonite all developed new IR spectral features around 900 cm⁻¹ when at 800°C. No similar new spectral features were observed for SWy-2 (2.68% MgO) montmorillonite at 800°C.

6. Summary and Conclusions

[73] This study documents the effects of heating phyllosilicates and zeolite minerals based on ATR, IR reflectance, TGA, and powder XRD measurements. Heat treatment produces distinct changes in the infrared spectral features (~100–4000 cm⁻¹) of phyllosilicates and zeolites. These changes are associated with dehydration and/or dehydroxylation processes, determined primarily by the specific crystal structures and affected by their octahedral and extrarframework cation compositions:

[74] 1. For phyllosilicate samples, the OH stretching (~3600 cm⁻¹), OH bending (~590–950 cm⁻¹), and/or H₂O bending (~1630 cm⁻¹) bands all become very weak or completely disappear upon heating to temperatures > 500°C. The spectral changes associated with SiO vibrations (~1000 cm⁻¹ and ~500 cm⁻¹) show large variations depending on the compositions and structures of phyllosilicates. Spectral features of kaolinite change significantly at ~400°C and the new bands are relatively stable until 900°C. Most smectite samples display two distinct spectral changes with increasing temperature, which may be related to their dehydration and dehydroxylation processes, respectively. Clinohore also exhibited dual changes in spectral features on heating, likely due to the presence of two different types of hydroxyl groups. The modulated tetrahedral sheets of palygorskite/sepiolite minerals showed more complex spectral changes on heating than other phyllosilicates included in this study. Compared to the phyllosilicates, the spectral features of two natural zeolites, clinoptilolite and mordenite, are less affected by thermal treatments. Even after heating to 900°C, the IR spectral features do not show significant differences from those of unheated zeolites. These spectral results are consistent with the fact that the three-dimensionally rigid crystal structure of zeolite is stabler than the layer structure of phyllosilicates.

[75] 2. The composition of octahedral sites showed a great influence on spectral behaviors of phyllosilicates: IR spectra of Al³⁺ rich smectites are stabler than those of Fe³⁺ rich smectites; spectral behaviors of Mg²⁺ rich phyllosilicates are distinctly affected by the formation of new crystal phases around 700°C; phyllosilicates with a small amount of Mg²⁺ on their octahedral sites all showed new spectral band at ~900 cm⁻¹ upon heating to 700°C or higher temperatures.

[76] Acknowledgments. This manuscript was greatly improved by the careful work of Editor Robert Carlson, and thorough reviews from Patricia Gavin and an anonymous reviewer, for which we are very grateful. We are also grateful for support from Mars Fundamental Research Program NNX08AN62G.
